

The Miranova Matrix

An Operational Framework for Emergent Structure

Exploring mediated constraint, admissibility, and simulation-oriented emergence

The Miranova Matrix presents an exploratory operational framework for investigating how persistent structure may emerge from minimal update rules in dynamical systems. Evolution is modelled as discrete irreversible “ticks,” each comprising distinctions and transformations that regulate commitment through mediated constraint and graded admissibility. Rather than proposing a new physical theory, Miranova is intended as a simulation-oriented grammar for emergence: a basis for computational experiments in constraint propagation, stability, and ordered complexity. References to known physical principles; such as causal ordering, irreversibility, and symmetry constraints, serve as interpretive guardrails, not derivations. The aim is to identify minimal mechanisms by which structured regimes can arise under physically compatible constraints, with illustrative mappings included only for context.

Reading Guide

Coherence – For an intuitive overview, follow the **blue** sections.

Resonance – For those who enjoy getting into the details, the **cyan** sections offer a more technical exploration.

Introduction

Many modern ideas in science suggest that space, time, and lasting structure may not be fundamental ingredients, but patterns that emerge from deeper processes. Rather than beginning with spacetime as a given stage, one can ask a simpler question:

What is the smallest kind of update a system must perform for persistence and complexity to arise at all?

This work explores that question through a minimal *operational* lens. Instead of starting with geometry or equations of motion, it begins with discrete irreversible steps; “ticks”, that distinguish, transform, and regulate state. Over repeated cycles, such updates can stabilise structure: regions of compatibility, constraint, and ordered persistence.

The Miranova Matrix is not proposed as a new physical theory, but as a simulation-oriented grammar for emergence; a structured way to explore how commitment and constraint can generate durable regimes over time. References to physical notions such as causality or irreversibility are used only as interpretive guardrails. The colour mappings used throughout are introduced as an operational representation; one possible way of encoding the framework’s participating degrees of freedom for clarity and eventual simulation, rather than as claims about fundamental properties of nature.

Figure 1: Conceptual depiction of emergent spacetime.

Operational and matrix-based formulations appear widely across physics and computation as compact representations of relational structure and irreversible transformations. Motivated by emergence programs in contemporary physics and complex systems, this work asks whether a minimal cycle of distinctions and transformations can serve as a useful operational basis for studying persistent structure under physically compatible constraints.

Conventional descriptions typically begin by assuming geometric or continuum structure. By contrast, the Miranova framework treats ordered update operations as primary, allowing persistence, causal depth, and structural regularities to arise from constraint-mediated update dynamics rather than being imposed as background. The result is a self-contained ledger of participation, intended for simulation, through which one may explore how constrained structure stabilises, how incompatibilities produce strain, and how ordered regimes emerge through mediated admissibility.

Motivation

The Miranova Matrix is presented as an operational grammar for emergent structure, specified independently of any particular physical theory. Nevertheless, it is useful to motivate the framework using familiar phenomenological patterns: the kinds of stable structure that embedded observers already encounter, and the possibility that such structure reflects deeper informational constraint.

The interpretive references that appear throughout this work are therefore not intended as derivations, but as orienting analogies: observational guardrails that help frame why a minimal operational ledger may be of interest.

Particle Phenomenology as Emergent Artifact

In an emergent spacetime setting, particle-like entities need not correspond to fundamental objects. They may instead arise as stable, repeatable artifacts of deeper operational constraint organisation: persistent modes of admissible commitment that appear as localised excitations to embedded observers.

The Standard Model is referenced throughout this work not as a derivation target, but as an observational catalogue of the most refined emergent regularities currently accessible. Its role here is exploratory: if the phenomena we call “particles” reflect structured artifacts of an underlying informational substrate, then existing particle phenomenology may offer a principled guide toward the number and character of degrees of freedom required for minimal operational emergence.

This interpretive perspective served as the original motivation for constructing the present operational framework.

Figure 2: Illustrates particle-like phenomena as emergent surface signatures arising from deeper ledger structure (interpretive metaphor).

Structure as Fruiting from Constraint Networks

A second motivation comes from the broader observation that visible structure often represents only the surface expression of deeper generative organisation. In biological systems, flowers emerge from root networks, and mushrooms fruit from extended mycelial substrates. What appears at the surface is not a primitive origin, but a localised manifestation of an underlying connectivity and constraint field.

This work treats ordered structure in a similar way: not as an assumed geometric background, but as something that may arise through patterns of admissible participation. The Participation Ledger provides a compact operational record of such participation, specifying how degrees of freedom are read, gated, and written across update events. Persistent “objects” may then be understood as stabilised configurations within this ledger, rather than as fundamental constituents.

Figure 3: Depicts realised phenomena as surface artifacts of deeper Participation Ledger structure, across biological and cosmological analogy (interpretive metaphor).

Transition to the Operational Framework

With these interpretive motivations in view, the remainder of the paper proceeds by specifying the minimal operational registers and update grammar required for emergent structure in simulation-oriented form: the nine Degrees of Freedom, the Tick primitive, and the seven fundamental operations through which commitment is traversed.

Core Primitives

- **Tick**

A tick represents a minimal *irreversible* update of the system, during which operational changes are applied and accumulated, independent of any external notion of time. In simulation, ticks need not occur synchronously, but may be realised through asynchronous local commitment events.

Figure 4: A tick represented as a series of ordered operations.

- **Identity / Distinction**

Identity is the persistence of a distinguishable structure across one or more ticks. Identities emerge when distinguishable patterns remain correlated across successive updates.

Figure 5: Identity represented as a distinguishable structure across ticks.

- **Causal depth**

Causal depth is the length of the longest irreducible chain of tick-ordered dependencies required for a structure to exist.

Figure 6: Causal depth as the longest chain of tick-ordered dependencies.

- **Branching / Clustering**

Branching refers to the divergence of causal sequences across updates, while clustering denotes the subsequent formation of correlated structure within that divergence.

Figure 7: Demonstration of branching and clustering across ticks.

- **Emergent time**

Embedded observers experience time primarily through the growth of causal depth and persistence, rather than through direct access to tick count.

Figure 8: Conceptual depiction of emergent time.

Key Principles

- **Monotonicity**
Operational updates establish causal precedence through ordered dependency, without requiring an external time metric or a globally synchronous clock.

Figure 9: Example of ordered dependency.

- **Irreversibility**
Certain operational distinctions, once introduced, cannot be fully undone in subsequent updates.

Figure 10: Example of irreversibility.

- **Dependency constraints**
Higher-order structures arise only after the completion of prerequisite operational sequences.

Figure 11: Example of higher-order structures.

- **Emergence principle**
Persistent structure arises when admissible distinctions stabilise through constraint-mediated commitment across repeated ticks.

Figure 12: Example of complex structure arising from ordered dependencies.

- **Observer embedding**
Observers exist as subsystems within the dynamics and therefore access only emergent, relational notions of time. The underlying update ordering remains internal and unobservable.

Figure 13: Example of an embedded subsystem.

Degrees of Freedom

When this framework refers to degrees of freedom, it is not describing spatial dimensions, hidden axes of the universe, or directions one could move through. Instead, degrees of freedom are best understood as independent aspects of a single state.

A simple analogy is a single pixel on a screen. One pixel is not many pixels, and it does not exist in multiple dimensions. Yet it can still be described using several independent values at once: how bright it is, what colour it is, how saturated that colour appears, or whether it is active at all. These values do not represent separate spaces, they are different attributes of the same pixel.

Figure 14: Multiple attributes of a pixel representing a single operational state.

In a similar way, the nine degrees of freedom in this framework can be thought of as nine descriptive *table columns* applied to a single operational state. Each degree of freedom captures a distinct mode by which a state may differ, persist, or influence subsequent updates. None of them alone defines the state, and none implies a separate dimension in which the system exists.

What matters is not the number of degrees of freedom, but the fact that they are independent yet co-present. Together, they describe how a state is structured, constrained, and able to evolve. The framework treats these degrees of freedom as operational descriptors and ways to characterise change, rather than as coordinates in a geometric space.

Nine Degrees of Freedom

Each Degree of Freedom denotes a distinct participatory register of operational state, expressed through Read, Gate, and Write roles across the Tick. Each item is defined operationally and does not presuppose semantic or cognitive interpretation:

1. **Coherence:** the degree to which relational structure is maintained across operational updates.
2. **Entropy:** the measure of dispersion or loss of constraint within operational structure.
3. **Activation:** the degree to which operations are permitted to proceed.
4. **Salience:** the degree to which expressed structure is prominent or influential within a given operational context.
5. **Excitation:** a globally conserved capacity for expression and mobilisation.
6. **Modality:** the categorical mode or representational form through which an operation is expressed.
7. **Stimulus:** an initiating perturbation that prompts operational response.
8. **Valence:** the directional weighting or bias applied to admissible selection.
9. **Resonance:** the degree to which interacting structures reinforce, cancel, or stably couple within operational dynamics.

Icons are mnemonic only, included for visual readability rather than ontological assignment.

Figure 15: Nine degrees of freedom and operational subspaces. Opposite vertices indicate complementary registers across subspaces.

Diagram Key

- Opposite vertices denote complementary registers across subspaces.
- Excitation is shown centrally as conserved capacity.
- The black/white split indicates Dynamics vs Disposition.

The Degrees of Freedom are arranged such that Dynamics and Disposition admit complementary duals, represented geometrically as opposite points rather than edge-adjacent couplings.

Excitation is treated as a conserved capacity field underlying participation, and is therefore shown as a central constraint rather than an edge register.

Operational Subspaces

1. **Dynamics** describes how change is locally expressed across operational updates, operating over shared generative structure while remaining subject to global constraints.
2. **Disposition** describes how expressed structure is differentially weighted across commitment history, biasing which identities or configurations tend to persist.

Both subspaces are jointly required: Dynamics expresses change, while Disposition shapes persistence.

The Tick Primitive

A **Tick** may be expressed formally as a directed traversal of operational transformations acting on distinctions. Rather than treating the seven operations as independent local steps, the framework represents each Tick as a single closed update cycle: an irreversible passage through admissible transformation and commitment.

In this representation:

- **Distinctions** appear as structural nodes, denoted Δ_i
- **Transformations** (operational updates) appear as directed edges, denoted O_i

The seven named phases of a Tick may therefore be written in verb-form as operators:

$$O_1 \text{ (Distinguish)} \rightarrow O_2 \text{ (Persist)} \rightarrow O_3 \text{ (Constrain)} \rightarrow O_4 \text{ (Disperse)} \\ \rightarrow O_5^c \text{ (Mediate)} \rightarrow O_6^x \text{ (Bias)} \rightarrow O_7 \text{ (Order)}$$

A Tick is then captured as a minimal structural object:

$$S := (\{\Delta_i\}_{i=1}^7, \{O_i\}_{i=1}^7)$$

with each transformation mapping one distinction into the next:

$$O_i : \Delta_i \rightarrow \Delta_{i+1} \pmod{7}$$

Cyclic indexing expresses closure of the operational traversal through modular identification, without introducing a privileged origin or implying reversibility. Irreversibility is carried globally by the directed orientation of the Tick.

Figure 16: Canonical Tick structure as a directed cycle of distinctions, connected by transformations. This operator skeleton provides the minimal substrate on which degrees of freedom participate.

Relation to the Participation Ledger

The Participation Ledger specifies how the Degrees of Freedom participate as reads, gates, and writes across each operator. It may therefore be understood as an operational record defined over the Tick skeleton above, summarising how commitment is structured through the seven fundamental operations.

Fundamental Operations

The fundamental operations described in this framework are not actions performed by an agent, nor are they physical forces, particles, or mental processes. Instead, they are best understood as basic modes by which a system can change or remain stable as it updates from one state to the next. An operation, in this sense, is not something that *does* anything on its own. It is a way of describing how change is permitted, constrained, or expressed during an update. Multiple operational roles may be relevant within a single update, shaping the same transition from different perspectives.

A helpful way to think about the operations in this framework is to imagine a simple dial lock. From the outside, the lock appears to have only one visible control: a dial that can be turned freely. i.e. a single degree of freedom. The dial may pass over the same positions many times, and it can end on the same number through different sequences of turns. Yet whether the lock opens or remains closed depends not on the final position alone, but on the particular sequence of movements that led there. In this sense, the *history* of operations matters just as much as the apparent configuration.

Figure 17: A sequence of operations acting on one degree of freedom.

The operations described here do not determine outcomes in isolation; what matters is how they are applied, in what order, and how their effects accumulate across successive ticks. Configurations that appear identical may differ in their operational history, and this hidden structure can determine whether a transition is permitted or a stable identity can persist. Visual illustrations are therefore used throughout as intuitive guides, helping to distinguish operational sequence from final configuration rather than serving as literal models.

These operations are termed fundamental because they form a minimal operational vocabulary sufficient to describe persistence, variation, and emergence, without assuming geometry, intention, or external time. The definitions that follow describe roles within state transitions and are intended to be read as complementary aspects of change, not independent controls or semantic meanings.

Seven Fundamental Operations

The seven fundamental operations define the minimal update grammar through which commitment is traversed within a Tick:

Operation	Icon	Description	Tick Placement
O₁ Distinguish	●	Undifferentiated → distinguishable structure Introduces difference where none was resolved. Marks the onset of asymmetry.	
O₂ Persist	○	Transient difference → stable identity Allows distinctions to survive across ticks. Stabilises continuity.	
O₃ Constrain	⌐	Free variation → constrained relational structure Limits which configurations remain admissible. Defines global compatibility.	
O₄ Disperse	⌐→	Local commitment → branching continuation Admits multiple admissible futures and structural propagation. Enables divergence under constraint.	
O₅^c Mediate (Consonance)	⌐↔	Isolated persistence → coupled dynamics Allows structures to condition one another through compatibility reference. Jointly shapes admissibility across registers.	
O₆^x Bias (Chirality)	⌐↔	Symmetric branching → orientational preference Introduces directional selection in continuation. Explains persistence without teleology.	
O₇ Order	⌐↔	Change → realised history Commits stable ordering on transformation itself. Asymmetry becomes structural record.	

Read, Gate, and Write

Within each operation, Degrees of Freedom participate in one of three functional roles:

- ← **Read**: referenced as contextual state
- ↔ **Gate**: conditions or constrains admissible transformation
- → **Write**: receives committed structural update

These roles do not represent local time steps, but relational participation within a single operational update event. Each operation realises a **conserved triadic grammar** of reference, constraint, and commitment, distributed across distinct Degrees of Freedom.

How to Read the Participation Ledger

The Participation Ledger that follows provides a compact operational summary of the framework. It describes how the Degrees of Freedom participate in an update event through functional roles, rather than as a causal or mechanically time-ordered process.

Each row corresponds to one of the seven fundamental operations (phases of a unified Tick), while the columns list the nine Degrees of Freedom as co-present registers of operational state.

The ledger is best read relationally:

- across a **row**, to see participation within an operation.
- down a **column**, to observe characteristic lifecycles, where Degrees of Freedom tend to appear first as read dependencies, later as gating influences, and finally as written commitments.

Excitation functions as conserved capacity: it is treated as a stable field constraint, read once as availability and propagated implicitly, and is therefore not repeatedly queried as an explicit operand.

Special Markers

Cross-constraint occurs at the level of reference within Mediation: admissibility is jointly conditioned, while writes remain register-specific and shaped downstream, not averaged upstream.

- **c Consonance**: **Mediation** is marked O_5^c , denoting compatibility-weighted reference (**read^c**).
- **χ Chirality**: **Bias** is marked O_6^χ , denoting orientational selection (**gate_χ**), later stabilised through **Ordering** (**write_χ**).

Operational Subspaces and Interpretive Layers

Each operation acts across two parallel subspaces (Dynamics and Disposition), applying the same operational grammar in complementary modes. Lower interpretive projections (e.g. BFSS or Standard Model analogues) are descriptive alignments only; the framework itself is fully specified by the Degrees of Freedom, operations, and participatory roles.

The Participation Ledger should therefore be read as an admissibility record: a summary of how ordered structure can emerge from minimal operational constraint, without presupposing spacetime geometry or external time.

Table 1: The Miranova Matrix is a participation ledger: a tabular encoding of how degrees of freedom enter each Tick as reads, gates, and writes.

Figure 20: Conceptual depiction of emergent spacetime interpreted as a projection of structured causal relationships.

Interpretation (Descriptive Alignments)

This section provides an interpretive overview of how the components of the framework relate once the operational primitives are in place. No new mechanisms are introduced. Instead, the intent is to clarify how change becomes expressible, how it is conditioned, and how persistent structure can arise through repeated admissible commitment.

At a high level, the framework distinguishes between:

- **Potential:** the space of admissible configurations the system can support, defined by the full set of Degrees of Freedom.
- **Generative Basis:** the shared substrate that enables expression at all.
- **Dynamics and Disposition:** complementary operational subspaces describing how change is locally realised and how persistence is shaped across updates.

While all nine Degrees of Freedom define the space of potential, **Excitation, Salience, and Modality** form a shared generative basis enabling structured expression without specifying its outcomes. Excitation functions as a conserved capacity field, while Salience and Modality characterise the prominence and representational mode through which expression occurs.

Dynamics and Disposition

- **Dynamics** describes how change is locally expressed across operational updates, operating over shared generative structure while remaining subject to global constraint.
- **Disposition** describes how expressed structure is differentially weighted across commitment history, biasing which identities or configurations tend to persist.

Neither subspace is sufficient in isolation. Together, they describe how expression and persistence arise from minimal operational participation under constraint, without presupposing external time or imposed geometry.

Geometric Projections (Octet Arrangement)

When multiple degrees of freedom must coexist under shared constraint, stable relational balances admit simple geometric projections. In Miranova, the Degrees of Freedom may be arranged in an octet-like symmetry: eight peripheral registers organised around a shared generative basis, with structured differentiation arising through admissibility, bias, and ordering.

Such octet projections are interpretive aids only. They do not introduce additional structure or assert physical correspondence, but serve as a compact map of relational balance within the operational space.

Interpretive Note: Matrix-Theoretic Inspiration (BFSS)

BFSS Matrix Theory is referenced only as an example of a non-geometric substrate in which spacetime is not fundamental. The Miranova framework does not depend on BFSS dynamics, nor does it claim derivation from brane constructions. Any labels or projections along such axes are intended solely as descriptive analogies for operational roles, not as assertions of novel physics.

Minimal Operational Emergence

From the primitives defined above, several minimal structural phenomena follow naturally in simulation-oriented realisations:

- continuity of distinction across ticks (**identity persistence**)
- admissible branching chains (**divergent commitment histories**)
- record-holding structure through ordering (**irreversible history**)
- **emergent subsystems** capable of internal differentiation (“observers” in the abstract operational sense)

The purpose of these notes is to emphasise that structured entities and histories may arise directly from the update grammar, without requiring additional imposed mechanisms.

Outlook Toward Simulation

The interpretive alignments above are descriptive only. The framework itself remains fully specified by its Degrees of Freedom, Tick primitive, and participation roles. With this operational core established, we now turn to simulation realisation: admissibility rules, gate families, excitation fields, and event-driven traversal mechanisms through which the Participation Ledger may be explored computationally.

Simulation Realisation

The Miranova Matrix is defined as an operational participation ledger: a minimal grammar specifying how Degrees of Freedom are read, gated, and written across update events. This structure is intended to be directly implementable in computational settings. The purpose of simulation is therefore not to add further primitives, but to explore what forms of persistent organisation arise when the ledger is enacted as an update process.

Simulation realisations proceed by specifying:

- i. an update traversal scheme,
- ii. admissibility and gate instantiations, and
- iii. capacity fields and boundary conditions under which commitment propagates.

Asynchronous Commitment Traversal

A key requirement is that commitment need not occur through synchronous global stepping. A fully synchronised “tick clock” implicitly introduces a preferred frame. Instead, updates may be realised as an asynchronous event-driven traversal, where simultaneity is not fundamental and ordering is local rather than global.

On this view, the Tick functions as a ledger abstraction: the invariant object is not a universal step index, but the local admissibility of commitment across the Participation Ledger.

Strain-Driven Event Scheduling

Update selection need not be random or externally forced. Commitment may instead be prioritised by unrealised compatibility pressure, or strain, defined as:

$$T = S_a (1-m)$$

where S_a denotes salience or mobilisation demand, and m denotes consonance (compatibility weight). Event priority may then be expressed as:

$$\text{Priority} = T \cdot E$$

Under this rule, updates occur preferentially where demand is high, consonance is low, and capacity remains available. Commitment therefore propagates as causal ripple structure through regions of maximal tension, without requiring stochastic noise injection.

Excitation as Conserved Capacity Field

Excitation is treated as a globally conserved capacity for expression rather than a repeatedly prescribed operand. In simple spatialised realisations, excitation may be modelled as a monotone availability field, for example as an inverse power-law capacity profile:

$$E(r) = \frac{1}{r^p}, \quad p > 0$$

Importantly, halo-like stability bands need not be imposed. Instead, persistent organisation may emerge in intermediate regions where excitation capacity and admissibility jointly balance. Inner regions may become incompatible under strain, while outer regions lack mobilisation strength, producing annular stabilisation as an emergent consequence of the operational rules.

The specific functional form is not essential; any smooth monotone decay may serve, with halo stabilisation emerging from admissibility balance rather than being imposed.

Topology and Persistent Flux

To sustain ongoing dynamics without external injection, simulations may adopt periodic or toroidal boundary conditions. Such topology permits conserved circulation modes, supporting persistent traversal without requiring randomness. Flux direction may be treated as an initial symmetry-breaking condition, while ordered persistence may be committed downstream through Bias and Ordering.

Closed damping cases may instead settle into quiescence, while toroidal regimes admit ongoing “everness” through conserved operational circulation.

Gate Families (Admissibility Variants)

The abstract Read/Gate/Write grammar does not prescribe a single functional gate form. Rather, gating may be instantiated through a family of admissibility operators, such as:

- threshold constraints (hard admissibility)
- graded compatibility kernels (soft admissibility)
- tension minimisation rules
- entropy/coherence trade-off filters
- chirality-selective bias gates

These variants do not alter the Participation Ledger itself, but provide implementational degrees of freedom through which different simulation regimes may be explored. Specific gate instantiations are left open, forming a natural axis of future simulation refinement.

Emergent Signatures (Testable in Simulation)

Because the framework is operationally specified, it suggests several qualitative signatures that should arise under broad initial conditions:

- robustness under asynchronous traversal (no preferred global tick frame)
- strain-front propagation rather than uniform updating
- halo-band stabilisation under monotone excitation fields
- chirality domain persistence once bias is introduced
- topology-sustained circulation under periodic boundary conditions

Such behaviours provide simulation-facing expectations through which the operational grammar may be refined and empirically constrained.

Toward Implementation

Simulation therefore functions as the next step of the framework: enacting the Participation Ledger as an event-driven commitment process. With admissibility rules, capacity fields, and gate instantiations specified, the Miranova Matrix becomes a computational object through which emergent structure, persistence, and constraint propagation may be systematically studied.

Structural Consequences

Within this operational setting, several structural consequences follow:

- **causal depth** provides an emergent basis for experienced time
- **branching commitment** supports rapid growth of complexity
- **iterated admissible updates** may generate ripple-like propagating structure

Concluding Context

The operational primitives and principles presented here define a *minimal framework* for reasoning about emergent structure, causal depth, and experienced time without presupposing spacetime geometry. By treating ordered operational updates as primary, the framework provides a coherent lens through which persistence, branching, and observer-embedded structure may arise from simple, irreversible processes.

Although developed at an abstract operational level, this framework is placed in dialogue with matrix-based approaches to fundamental physics, such as BFSS Matrix Theory, in which spacetime is likewise understood as emergent rather than fundamental. In this context, the Miranova Matrix does not propose any modifications to BFSS dynamics, nor does it attempt to derive physical observables. Instead, it offers a complementary conceptual vocabulary for articulating how ordered updates, causal depth, and interpretability may underwrite emergent temporal and structural features within matrix formulations.

The framework is intentionally limited in scope and generative in character. Its purpose is not to replace existing physical models, but to clarify relationships between causality, emergence, and embedded observation in systems where spacetime is not assumed. Further exploration may examine how such operational descriptions relate to specific matrix dynamics, physical observables, or computational implementations.

In this sense, the Miranova Matrix is offered as a structural lens rather than a completed theory, and its continuation, whether through formalisation, reinterpretation, or application, is left open to the broader community.

Open Questions

The framework is intentionally limited in scope. In particular:

- Absolute tick count may not be inferred from within the system.
- The behaviour of multiple clocks, extreme self-reference, and deep branching regimes is left undefined.
- Future work may explore connections to physical observables, dynamical models, or computational implementations.

Definitions

- **Miranova**

Combines **Mira**, the binary star system Mira A and Mira B, characterised by long-period variability and coupled stellar dynamics. With **nova**, in the sense of supernova, denoting large-scale emergent transformation arising from accumulated structure. The name reflects a framework concerned with variability, coupling, and the emergence of new structure from underlying relational dynamics, rather than the introduction of new fundamental physical law.
